### Introduction

#### 1.1 Motivation

#### 1.2 Aims and Objectives

#### 1.3 Overview

In Chapter 2, we provide a self-contained technical background on the key concepts and methods used in this project. Given the breadth of the topic, references are included for those looking to delve deeper into the subject.

In Chapter 3, we outline the experiments conducted in Chapter 4 to evaluate the performance of the numerical approximation methods. We detail the implementation of the methods and the experimental setup, including parameter selection and the benchmarking process We then provide the results on a list of transform pairs and discuss the implications of the findings.

In Chapter 5, we summarize the findings of the project and discuss potential avenues for future work. This allows for ...

# Background

In Chapter 2, we establish a foundational understanding of the topic in hand. This section is designed to be self-contained, providing essential background for all readers, while references are included for those seeking a deeper exploration.

"By definition, a complex number z is an ordered pair (x,y) of real numbers x and y, written z=(x,y)" (Kreyszig, 2010). In practice, complex numbers are written in the form z=x+iy, where x and y are real numbers and i is the imaginary unit. We may find it easier to represent complex numbers in their polar form,  $z=re^{i\theta}$ , where r represents the magnitude of z and  $\theta$  represents the angle of z with respect to the positive real axis. The set of complex numbers is denoted by  $\mathbb{C}$ .

#### 2.1 The $\mathcal{Z}$ -Transform

The z-transform is a transformation of a real or complex time function x(n), often used for analyzing discrete-time signals and systems. It is a generalization of the discrete-time Fourier transform (DTFT) that extends the analysis to the complex plane. The Z-transform is formally defined as:

$$X(z) = \mathcal{Z}_{n \to z}[x(n)] = \sum_{n = -\infty}^{\infty} x(n)z^{-n}$$

$$(2.1)$$

For a convenient description of z in the complex plane, we tend to its polar form  $z = re^{i\theta}$ .

In the analysis of causal systems - systems for which a time origin is defined and is illogical to consider signal values for negative time - the unilateral z-transform is used. Unlike the bilateral z-transform in Eq. (2.1), we sum from zero to positive infinity yielding

$$X(z) = \mathcal{Z}_{n \to z}[x(n)] = \sum_{n=0}^{\infty} x(n)z^{-n}$$
 (2.2)

The region within the complex z-plane where the z-transform converges is known as the Region of Convergence (ROC). The ROC is defined for the set of values of z for which the z-transform is absolutely summable

$$\mathbf{ROC} = \left\{ z : \sum_{n=0}^{\infty} |x(n)z^{-n}| < \infty \right\}$$
 (2.3)

For causal sequences, the ROC is typically the exterior of the outermost pole in the Z-plane,

denoted as |z| > a. If we say that  $z_1$  converges, then  $z_1$  exists within the ROC. Thus, all z such that  $|z| \ge |z_1|$  also converge. This region excludes the poles themselves, as the transform does not converge at those points. For the system to be stable, the ROC must include the unit circle, |z| = 1, implying that all poles must lie within the unit circle (Loveless and Germano, 2021).

#### 2.1.1 Relation to the Fourier Transform

It is useful to note the relationship between the z-transform and the Fourier transform. Taking the Fourier transform of a sampled function x(t) results in:

$$\mathcal{F}\left[x(t)\sum_{n=-\infty}^{\infty}\delta(t-n\Delta t)\right] = \int_{-\infty}^{\infty}x(t)\sum_{n=-\infty}^{\infty}\delta(t-n\Delta t)e^{-i\omega t}dt$$
 (2.4)

$$= \sum_{n=-\infty}^{\infty} \int_{-\infty}^{\infty} x(t)\delta(t - n\Delta t)e^{-i\omega t}dt$$
 (2.5)

$$=\sum_{n=-\infty}^{\infty} x(n\Delta t)e^{-i\omega nt}$$
 (2.6)

where we make use of the sifting property of the delta function. If we normalize the sampling interval to 1, we get

$$\sum_{n=-\infty}^{\infty} x(n)e^{-in\omega} \tag{2.7}$$

This is the discrete-time Fourier transform (DTFT) of the sequence x(n). The sequence x(n) is sampled at discrete-time intervals  $t_n = n \triangle t$ , where the sampling interval  $\triangle t$  is the time between consecutive samples and the time index n numbers the samples. The DTFT is a periodic function of  $\omega$  with period  $2\pi$ , and its existence relies on the absolute summability of the sequence x(n):

$$\sum_{n=-\infty}^{\infty} |x(n)| < \infty \tag{2.8}$$

The Z-transform generalizes Eq. (2.7) to the complex plane, not just the unit circle where r = 1 (Schafer and Oppenheim, 1989).

#### 2.1.2 Relation to Probability Distribution Functions

Random events and signals refer to situations where the outcome is not deterministic, but can be described by probability. Understanding these concepts involves using Probability Distribution Functions; the Probability Mass Function (PMF) for discrete random variables and the Probability Density Function (PDF) for continuous random variables. Given the nature of this project, we'll be focusing our attention on the PMF.

The PMF is defined for a discrete random variable X taking on values  $x_i$  with probabilities  $p_i$ , as  $P(X = x_i) = p_i$ . The PMF satisfies the following properties:

$$\sum_{i=0}^{n} p_i = 1 \quad \text{and} \quad 0 \le p_i \le 1 \ \forall i$$
 (2.9)

We may find it useful to provide a concise representation of the entire distribution such that we expand upon the PMF, p(x), to obtain the Probability Generating Function (PGF),  $G_X(q)$ ,

defined as

$$G_X(q) = E[q^X] = \sum_{x=0}^{\infty} p(x)q^x,$$
 (2.10)

where  $E[\cdot]$  denotes the expectation operator, and q is a complex number. We deliberately use q to distinguish the PGF from the z-transform (Eqn. 2.1)

**Example 1** Consider a fair six-sided dice. The PMF for the dice roll is given by

$$p(x) = \begin{cases} \frac{1}{6} & if \ x = 1, 2, 3, 4, 5, 6\\ 0 & otherwise \end{cases}$$
 (2.11)

where p(x) is the probability of rolling a number x. The PGF for the dice roll is then

$$G_X(q) = \sum_{x=0}^{\infty} p(x)q^x = \frac{1}{6} \sum_{x=1}^{6} q^x = \frac{q}{6} \cdot \frac{1-q^6}{1-q},$$
 (2.12)

where we use the formula for the sum of a geometric series. The PGF encapsulates the entire distribution of the dice roll into a single function.

The concept of summarizing information is not unique to probability theory. In the analysis of signals, we aim to encapsulate the behaviour of a sequence into a single function. This is akin to the PGF, where the z-transform is used to analyze discrete-time signals and systems. Drawing on the principles outlined by Ross (2014), we can bridge the gap between probability theory and signal processing, leveraging the z-transform to analyze the behaviour of signals in the complex plane.

#### 2.2 The Inverse $\mathcal{Z}$ -Transform

The inverse Z-transform aims to find the n-th value of the sequence x(n) given the Z-transform X(z). This is commonly defined as a Cauchy integral around a contour C in the complex plane. The contour C is a counter-clockwise closed path that encloses the region of convergence (ROC). The inverse Z-transform is formally given by

$$x(n) = \mathcal{Z}_{z \to n}^{-1}[X(z)] = \frac{1}{2\pi i} \oint_C X(z) z^{n-1} dz$$
 (2.13)

In practical settings, numerical approximations are often used due to the computational challenges of evaluating the Cauchy integral. Whilst there are many ways to go about this (Merrikh-Bayat, 2014; Rajković et al., 2004; Horváth et al., 2020), most methods are done on a circular contour. Aligning with the focus of our project, we shift our attention to contour integrals.

#### 2.2.1 Abate and Whitt 1992

The numerical approximation formula offered by Abate and Whitt (1992a,b) is based on a Fourier series catering to the inversion of probability generating functions as elucidated in Section 2.1.2. The format is conducive to queuing theory and other probabilistic models where the Z-transform is defined as q = 1/z. The authors approximate the inversion using a trapezoidal rule for numerical integration over a complex contour given by

$$x(n) \approx \frac{1}{2nr^n} \left( X(r) + 2\sum_{k=1}^{n-1} (-1)^k \operatorname{Re}\left( X(re^{\frac{ik\pi}{n}}) \right) + (-1)^n X(-r) \right)$$
 (2.14)

The parameter r is used to control the error; setting  $r = 10^{-\lambda/2n}$  yields an accuracy bound of  $10^{-\lambda}$ . The authors leverage the inherent symmetry within the complex plane to enhance computational efficiency by exploiting the complex conjugate symmetry of X(z); each term  $X(re^{\frac{ik\pi}{n}})$  in the upper half has a mirror image in the lower half. The computational load is thus halved by folding the problem in this manner.

Given the nature of this project, we may find it easier to use the following definition, where we set z = 1/q, to approximate Eq. (2.13).

$$x(n) \approx \frac{1}{2nr^n} \left( X(\frac{1}{r}) + 2\sum_{k=1}^{n-1} (-1)^k \text{Re}\left( X(\frac{1}{re^{\frac{ik\pi}{n}}}) \right) + (-1)^n X(-\frac{1}{r}) \right)$$
(2.15)

The Nyquist-Shannon sampling theorem states that a signal must be sampled at a rate of at least twice the highest frequency present in the signal to avoid aliasing (Shannon, 1949; Nyquist, 1928). The number of points, n, used in Eqn. (2.15) must be sufficient to capture the information properly. If n is too small, the approximation may lead to inaccuracies - akin to aliasing in signal processing.

#### 2.2.2 Cavers 1978

Extending upon our analysis in Section 2.1.1, Cavers (1978) proposes to sample the z-transform of a function on a circular contour at equally spaced points and then apply the inverse FFT to these sampled points to approximate the original time-domain signal. We can formulate this as:

$$f(n) = r^n \text{IFFT}[f(re^{2\pi i/N})], \tag{2.16}$$

where r is the radius of the circular contour, n is the time index, and N is the number of points used in the DFT. The factor  $r^n$  scales the result appropriately based on the radius of the contour.

#### 2.2.3 Series acceleration techniques

#### 2.3 Option Pricing

The concept involves determining the value of options, which are financial contracts that give the holder the right, but not the obligation, to buy or sell an asset at a set price within a specified time-frame. The value of an option is derived from the underlying asset, which can be a stock, bond, or commodity.

A pivotal point in option pricing was the introduction of Black and Scholes (1973)'s model in estimating the price of European-style options, which can only be exercised at the expiration date. The Black-Scholes model is based on the assumption that the price of the underlying asset follows a geometric Brownian motion in idealistic conditions. However, many options traded in real markets are American-style, allowing the holder to exercise the option at any time before the expiration date. This complicates the pricing process as it involves solving an *optimum stopping problem*. Merton (1973) extends the Black-Scholes model to American options by expressing the price as the solution to a free boundary problem. While Merton's work provided a theoretical foundation, solving the free boundary problem analytically is challenging. Instead, numerical methods such

as binomial trees (Cox et al., 1979) and simulation-based methods (Longstaff and Schwartz, 2001) have been developed to price American options.

#### 2.3.1 Discrete Monitoring

In most cases, the payoff of an option depends on the price of the underlying asset at discrete points in time rather than continuously. This is known as discrete monitoring. Two widely traded types of discretely monitored options are lookback and barrier options (Dadachanji, 2015). These options are classified as *exotic options* where the payoff is based on the path of the underlying asset price rather than just the price at expiration.

#### 1. Barrier Options

The payoff depends on whether the price of the underlying asset reaches a certain level (the barrier) during the life of the option. A *knock-in* barrier option only come into existence if the barrier has been touched, while a *knock-out* barrier option ceases to exist instead. For example, a *down-and-out* barrier option is a type of knock-out option that becomes worthless if the price of the underlying asset falls below the barrier level. On the other hand, a *down-and-in* barrier option is a type of knock-in option that only becomes active if the asset price falls below the barrier level.

#### 2. Lookback Options

The payoff depends on the maximum and minimum asset price over the life of the option. A lookback call option gives the holder the right to buy the asset at the lowest price during the option period, while a lookback put option allows the holder to sell the asset at the highest price during the option period.

#### 2.3.2 Fourier-Based Pricing

However, the pricing of these options can be computationally expensive due to the high-dimensional integrals involved in the pricing formulas. Carr and Madan (1999) was the first to propose using Fourier transforms to price European options. It involved transforming the pricing problem from the time domain to the frequency domain, where the pricing formula simplifies to a one-dimensional integral.

- talk about the advancements of Fourier transforms in option pricing
- mention the linear dependence of the investigated ways
- lead on to Fusai et al. (2006)
- look into Plancherel's theorem
- talk about Phelan's extension
- end off with why we're looking into the inverse Z-transform

#### 2.4 Optimization Techniques

In the context of computational mathematics, optimizations techniques are used to identify the optimal or a sufficiently effective solution to a problem within a given set of constraints. The goal

is to minimize or maximize a specific objective function by systematically choosing the values of the variables. The objective function is often referred to as the *cost function* or *loss function* and the variables are referred to as *parameters*. The optimization problem can be formulated as

minimize 
$$f(x)$$
 subject to  $x \in \Omega$  (2.17)

where f(x) is the objective function and  $\Omega$  is the feasible region defined by the constraints of the problem.

Gradient descent is one of the most popular algorithms for parameter optimization with success in Deep Learning and Neural Networks employing variants of the algorithm (Lu and Jin, 2017; Zhang, 2019; Zeebaree et al., 2019). The adaptability to diverse problem domains (Tian et al., 2023) parallels our use case, where gradient descent is applied outside traditional deep learning to optimize parameters of a mathematical function (Persson et al., 2022).

#### 2.4.1 Gradient Descent

Gradient descent iteratively converges to a local minimum of a function by moving in the direction of the steepest descent, as defined by the negative gradient. This method is expressed mathematically as

$$x_{k+1} = x_k - \alpha_k \nabla f(x_k) \tag{2.18}$$

where  $x_k$  is the parameter vector at iteration k,  $\alpha_k$  is the learning rate, and  $\nabla f(k)$  represents the gradient of the function at  $x_k$ . The selection of  $\alpha_k$  determines the size of the step taken towards the minimum; too large can overshoot the minimum, too small can result in a long convergence time. The process repeats until a predetermined termination criterion is met, typically when the change in the value of f(k) falls below a threshold. This iterative process is showcased in the pseudocode below:

#### Algorithm 1 Gradient Descent

- 1: Initialize  $x_0$ , set k=0
- 2: while termination conditions not met do
- 3: Compute gradient  $\nabla f(x_k)$
- 4: Choose a suitable step size  $\alpha_k$
- 5: Update  $x_{k+1} = x_k \alpha_k \nabla f(x_k)$
- 6: k = k + 1
- 7: end while

#### Stochastic Gradient Descent

However, classic Gradient Descent faces limitations, including susceptibility to local minima and potential for overshooting or long convergence times. Stochastic Gradient Descent (SGD) addresses these issues by introducing variability in the optimization process. It modifies Eq. (2.18) to use a randomly selected subset of data to compute the gradient, to allow for dynamic adjustment of the learning rate and leveraging noise to escape local minima. We define the update rule to

$$x_{k+1} = x_k - \alpha_k \nabla f_{i_k}(x_k) \tag{2.19}$$

where  $\nabla f_{i_k}(x_k)$  is the gradient of the cost function with respect to a random subset  $i_k$ . We thus avoid the pitfalls associated with a static learning rate and promote a quicker convergence time.

# Experiment

Having established the theoretical foundation, we now turn our attention to the practical implementation of methods proposed by Abate and Whitt (1992a,b) and Cavers (1978). Whilst the former is based on a circular contour, we also explore the idea laid out by Boyarchenko and Levendorskii (2022) in sampling the z-transform on a sinh-deformation.

This chapter outlines the experimental setup, implementation and evaluation of the methods. We measure our results in terms of accuracy, computational efficiency, and robustness to parameter changes in an attempt to provide a thorough comparison of the methods to determine the most effective approach.

If we get series acceleration, include here asw

#### 3.1 Sinh Deformation

"The inverse at point T can be obtained from the contour integral where C is a counter-clockwise closed path encircling the origin and entirely in the region of convergence." (Horváth et al., 2020). A circular contour integral is commonly used for approximating the inverse z-transform as we've seen in Section 2.2.1 and 2.2.2. However, this does not mean it may be the best option.

- introduce Levendorskii's sinh deformation
- $\bullet\,$  talk about why he does this

#### 3.1.1 Deforming the Contour

- explain the sinh deformation
- provide plots of the effects of the parameters understanding
- $\bullet$  talk about the implications of the deformation (sufficient conditions)

#### 3.1.2 Parameter Grid Search

- use of grid search to find optimal parameters
- different search criteria's (e.g. area, x-axis perimeter, etc)
- might also be useful to try find parameters that give the results?
- use of SGD and loss function

### 3.2 Numerical Benchmarking

Function	x(z)	X(z)
Heaviside Step	1	z/(z-1)
Polynomial	t	$z/(z-1)^2$
Decaying Exp	$e^{-at}$	$1/(1 - \exp(a\triangle t)z^{-1})$
Sinusoidal	$\sin(\omega t)$	$(z^{-1}\sin(w\triangle t))/(1-2z^{-1}\cos(w\triangle t)+z^{-2})$

Table 3.1: List of Transform Pairs

# Aims and Objectives

#### 1.1 **Aims**

We aim to understand a new efficient method for numerical evaluation of the inverse Z-transform, which states to be faster and more accurate than the standard trapezoid rule. A specific area of applying this method would be to the pricing of discretely monitored exotic options, such as lookback and barrier options, and see how it compares to other methods; Abate and Whitt's approach, C. Cavers' method with Euler, Shanks and epsilon accelerations, etc.

#### 1.2 Objectives

- Understanding Levendorskii's inverse Z-transform and the common numerical evaluation methods
- Implementing the function as a code
- Numerical benchmarking; average error, maximum error and CPU time
- Exploring its uses in discrete pricing options

#### 1.3 Deliverables

- numerical benchmarking results to add to 'Review of numerical inversion techniques of the z-transform' by Loveless and Germano
- results and implementation in regards to discrete pricing options (Accurate numerical inverse z-transform and it's use in the Fourier-z pricing of discretely monitored path-dependent options by Loveless, Phelan and Germano)

### Work Plan

### 2.1 Project Start $ightarrow 30^{ m th}$ November '23

- background reading on complex numbers & contour integration based methods, fourier transform, z-transform and its inverse, numerical approaches to inverse z-transform and pricing options (barrier and lookback options)
- $\bullet$  coding implementation of Levendorskii's inverse z-transform

### $2.2 \quad 1^{\mathrm{st}} \; \mathrm{December} \; `23 ightarrow 24^{\mathrm{th}} \; \mathrm{January} \; `24$

- preliminary research on Loveless' and Germano's 'Review of numerical inversion techniques of the z-transform'
- understanding the other methods; AW, C, CEuler, CShanks and CEpsilon
- going over the different functions; Heaviside Step, Polynomial, Decaying Exp, Sinusodial
- reviewing the code for numerical benchmarking
- implementing it for Levendorskii's method
- begin work on interim report

### 2.3 $24^{\rm th}$ January '24 $\rightarrow$ 15<sup>th</sup> March '24

- ullet preliminary recap on discrete pricing options (barrier and lookback options) and the need for z-transform
- use-case in discrete pricing options
- start work on project report; however, to be worked on throughout the year/stages

### $2.4~~5^{th}~March~`24 ightarrow 26^{th}~April~`24$

- extra time to deal with any unexpected problems or delays
- final touches
